Abstract

Secure join queries over encrypted database, the most expressive class of SQL queries, have attracted extensive attention recently. The state-of-the-art JXT (Jutla et al. ASIACRYPT 2022) enables join queries on encrypted relational database without pre-computing all possible joins. However, JXT can merely support join queries over two tables (in encrypted database) with some high-entropy join attributes.

In this paper, we propose an equi-join query protocol over two tables dubbed JXT+, that allows the join attributes with arbitrary names instead of JXT requiring the identical name for join attributes. JXT+ reduces the query complexity from $O(\ell_1 \cdot \ell_2)$ to $O(\ell_1)$ as compared to JXT, where ℓ_1 and ℓ_2 denote the numbers of matching records in two tables respectively. Furthermore, we present JXT++, the *first* equi-join queries across three or more tables over encrypted database without pre-computation. Specifically, JXT++ supports joins of arbitrary attributes, i.e., all attributes (even low-entropy) can be candidates for join, while JXT requires high-entropy join attributes. In addition, JXT++ can alleviate sub-query leakage on three or more tables, which hides the leakage from the matching records of two-table join.

Finally, we implement and compare our proposed schemes with the state-of-the-art JXT. The experimental results demonstrate that both of our schemes are superior to JXT in search and storage costs. In particular, JXT+ (resp., JXT++) brings a saving of 49% (resp., 68%) in server storage cost and achieves a speedup of 51.7× (resp., 54.3×) in search latency.

1 Introduction

Encrypted search protocol enables the client to perform efficient search over encrypted database. Symmetric searchable encryption (SSE), initiated by Song et al. [35], is a promising primitive for realizing efficient encrypted search, which has been extensively studied in the past two decades [9–13, 20, 21, 25, 32, 36, 37]. A long line of research has been conducted to achieve better tradeoffs between security, functionality, and performance by revealing well-defined leakage information.

We note that, however, almost all SSE constructions support only keyword-based search on encrypted documents. As claimed in [25], most real-world data is usually stored and shared in relational databases. Roughly speaking, a relational database is a collection of tables with rows representing records and columns representing attributes, and most relational databases are equipped with the structured query language (SQL) for data querying and updating. A significant puzzle to be solved is how to perform expressive queries on encrypted relational database [25].

Hacigümüş et al. [18] first explicitly initiated the study of search on encrypted relational databases, where each attribute domain is split into a sequence of buckets and the associated bucket of the queried data will be returned. In 2011, Popa et al. [32] developed a SQL-aware encrypted database system called CryptDB, that can support a large class of SQL queries by assembling property-preserving encryption (PPE). Nevertheless, it has been witnessed in [29] that the PPE-style approach is vulnerable to leakage-abuse attacks.

Table 1: Comparison with prior secure join schemes.

Assume that the database consists of two tables, Tab₁ and Tab₂, and each has m rows, n columns, and T join attributes. We consider performing a query $q = (\text{Select } inds \text{ From Tab}_1, \text{Tab}_2 \text{ Join On } attr_1^* = attr_2^* \text{ Where } w_1 \wedge w_2)$. The symbols \P , \P , and Q denote fully, partially, and without pre-computation of all possible joins, respectively. Let $\ell_i = |\text{DB}_{\text{Tab}_i}(w_i)|$, and ℓ_{max} is the maximum occurrence number of the combinations of each join-attribute value of ℓ_{max} and all attribute-value pairs in Tab₁. ℓ_{max} is the search result of the query ℓ_{max} is the search result of the join query ℓ_{max} (Select ℓ_{max} From Tab₁, Tab₂ Join On ℓ_{max} is the pseudorandom function operation, ℓ_{max} is the decryption operation for symmetric encryption algorithm, ℓ_{max} is the hash function, ℓ_{max} is the exclusive-or operation. EMM ℓ_{qry} refers to the operation of retrieving an entity from the encrypted multi-map, and ℓ_{max} for the equality test over plaintext.

†: If $|R_I| = \emptyset$, the server computation can be reduced to constant (i.e., O(1)).

To mitigate the leakage of join queries, Kamara et al. [25] introduced the first structured encryption scheme supporting join query named SPX, which relies crucially on pre-computing all possible joins and storing all the result in encrypted version of database. While it achieves optimal search complexity, SPX brings non-trivial storage overhead in some cases, especially when the number of join attributes in the database is large and the value distribution has a very low entropy across all joinable attributes. That is, the lower entropy across join attributes, the larger the number of possible joins in pre-computation mode. Thus, SPX tends to configure high-entropy attributes as join attributes for storage efficiency. Subsequently, Cash et al. [11] presented a variant of SPX by introducing the technique of *partially pre-computed joins*, which can achieve less leakage and communication size at the expense of moderate client-side computation.

Recently, Jutla et al. [22] presented JXT, a novel join queries scheme without join pre-computation. Specifically, inspired by OXT [10], this protocol generates two new table-wise data structures TSet and XSet for each table, where TSet refers to an inverted index for attribute/value pairs to perform single-keyword search within a single table, and XSet contains all combinations of record identifier/join-attribute value pair. The basic idea is to retrieve the corresponding record identifiers matching the queried keywords for two tables, respectively. Later, the server computes all the crosscombinations of the matching record identifiers and join-attribute value pairs between two tables, and checks whether the above combinations belong to the XSet. Thus, the query complexity is $O(\ell_1 \cdot \ell_2)$, where ℓ_1 and ℓ_2 denote the numbers of matching records in two tables. Although JXT can achieve two-table join queries without pre-computation, it requires the joinable attributes across tables with the same attribute-name (i.e., natural join). In addition, JXT cannot be trivially extended to three or more tables due to the complication of generating join tokens on three or more tables.

In this work, we further investigate secure equi-join queries over encrypted database without join pre-computation that can support low-entropy join attributes, even handle *three or more* tables. More precisely, it performs SQL queries in the following form:

Select *inds* From *tables* Join On
$$(attr_1^* = ... = attr_k^*)$$

Where $(w_1 \wedge ... \wedge w_k)$,

where *inds* denote record identifiers, $attr_i^*$ refers to the join attribute of table Tab_i in database, and w_i is the attribute-value pair.

1.1 Our Contributions

In this paper, we make affirmative progress to secure join queries over encrypted relational database without pre-computation. Specifically, we propose an efficient equi-join query scheme over two tables and further extend to scalable equi-join queries across three or more tables. Both of the constructions outperform the state-of-the-art JXT [22] in terms of query complexity and storage overhead. In addition, similar to JXT [22], our protocols can support flexible table addition by constructing index for newly added table separately, while SPX [25] requires to perform the setup process across all tables. Table 1 shows a brief comparison with prior works. More concretely, our main contributions can be summarized as follows:

- We propose JXT+, which supports equi-join queries over two tables without join pre-computation. Compared with the state-of-the-art JXT [22], JXT+ allows join attributes with arbitrary names, as opposed to the identical join attribute name in JXT. The query complexity of JXT+ is reduced from O(ℓ₁ · ℓ₂) to O(ℓ₁), where ℓ₁ and ℓ₂ are the numbers of matching records in the two queried tables. In addition, JXT+ can avoid the leakage information on join attributes by binding non-join-attribute value and join-attribute name in TSet.
- We present JXT++, to our best knowledge, the *first* equi-join queries over three or more tables without pre-computation.
 In particular, JXT++ can achieve join of arbitrary attributes

even low-entropy attributes, eliminating the limitation of high-entropy join-attribute in JXT. Moreover, JXT++ can mitigate the sub-query leakage, stemming from multiple-table join, while surpassing JXT in query and storage efficiency.

• We implement our two protocols and perform a comprehensive comparison with the state-of-the-art JXT [22]. The experiment results demonstrate that both of our schemes outperform JXT in terms of query time and storage cost. Particularly, JXT+ (*resp.*, JXT++) brings a saving of 49% (*resp.*, 68%) in server-side storage cost and achieves a speedup of 51.7× (*resp.*, 54.3×) in search latency.

1.2 Technical Overview

Equi-Join Queries over Two Tables. Inspired by OXT [10], JXT [22] mainly construct two data structures, TSet and XSet, for each table in database. Here, TSet serves as an inverted index for all attribute-value pairs, while XSet contains all combinations of record identifier and join-attribute value pair. The essential idea of JXT is to retrieve the records matching with specific attribute-value pair from the TSet of table Tab₁ (resp. Tab₂), and then determine if the matching records from Tab₂ can be joined with those from Tab₁. This is achieved by checking whether the combinations of identifiers of ℓ_2 matching records from Tab₂ and join-attribute value pairs of ℓ_1 matching records from Tab₁ appear in the XSet. In addition, we note that the queried join attributes in JXT must be sent to the server to locate the corresponding entry in TSet, which leads to some extra leakages, i.e., the queried join attributes. Overall, JXT suffers from heavy join query complexity $O(\ell_1 \cdot \ell_2)$ and cannot handle equi-join query because the join-attribute name and value are jointly stored into XSet for each record.

To support equi-join queries, a trivial solution is to decouple the join-attribute name from its corresponding value in JXT. Specifically, all join-attribute value pairs, in TSet and XSet, can be split into two components: join-attribute name $attr^*$ and join-attribute value w^* . Informally speaking, the original combination $(ind, attr^* = w^*)$ is replaced with a triple of $(ind, attr^*, w^*)$, where the record identifier ind and join-attribute name $attr^*$ are from one table and join-attribute value w^* from another. Here, the only required change to achieve join with different join-attribute names is to include both queried join attribute names in search token. However, this approach still requires to perform single-keyword search on both tables and then join on their results, resulting in $O(\ell_1 \cdot \ell_2)$ query complexity. Meanwhile, the queried join-attributes will be revealed.

We observe that equi-join can be achieved by checking the combination of join-attribute name and join-attribute value from different tables (e.g., $(attr_1^*, w_2^*)$). To further reduce join cost, our initial idea is to build TSet to store all combinations of attribute-value pair and join-attribute value (e.g., (w_1, w_1^*)) in each table, which is indexed by the combination of attribute-value pair and any possible join-attribute name. Then, the join can be done by checking the combination of $(w_1^*, w_2, attr_2^*)$ in XSet. Note that only a single table is queried, the query complexity is reduced to $O(\ell_1)$. Further, we introduce an additional data structure CSet indexed by the combination (e.g., $(w_1, w_1^*, attr_1^*)$) for each table, which stores "together" all the corresponding encrypted record identifiers. Thus, all the matching identifiers can be retrieved at constant cost. In addition,

our solution can hide the join-attribute information by binding it with non join-attribute value in TSet (i.e., $w||attr_t^*|$).

Equi-Join Queries over Multiple Tables. An open question, "How to extend JXT to support join queries over *three or more* tables without join pre-computation?" is posed by Jutla et al. [22]. A straightforward answer is to divide the whole database into a collection of subsets including two designated tables and execute JXT protocol on them, then filter out the final result locally. Specifically, given a database with N tables $(\mathsf{Tab}_1,\ldots,\mathsf{Tab}_N)$, to achieve join queries over k tables, the client performs JXT protocol repeatedly on table pairs of $(\mathsf{Tab}_1,\mathsf{Tab}_i)_{i\in[2,k]}$. After that, the client decrypts all the record identifiers matching with each two-table join and determines the final result by obtaining the intersection. However, this naïve solution suffers from heavy query cost, i.e., $O(\sum_{i=2}^k \ell_1 \cdot \ell_i)$, where ℓ_i denotes the numbers of matching records in Tab_i .

To achieve efficient equi-join over multiple tables, our starting point is to extend our proposed JXT+ to support multiple-join queries. Specifically, the client first retrieves ℓ_1 entries matching w_1 from TSet in Tab₁, and then to check whether the combinations $(w_2, attr_2^*, w_1^*), \dots, (w_N, attr_k^*, w_1^*)$ include in XSet, where join-attribute value w_1^* is from Tab₁, attribute-value pairs $(w_2, \ldots,$ w_k) and attribute names $(attr_2^*, \dots, attr_k^*)$ are from the rest k-1tables. When all checkings are passed, the client obtains the final result by retrieving all the matching record identifiers from all the k tables. Obviously, the query cost is only dependent on the matching record identifiers in the first table, i.e., $O((k-1)\ell_1)$. Nevertheless, this simple extension of JXT+ leaks non-trivial leakage. Particularly, the server might learn sub-query leakages¹, i.e., all the record identifiers matched with each two-table join. Additionally, it also leaks the frequency of join-attribute values associated with the queried attribute-value pairs, i.e., the number of occurrences of (w, w^*) , which is more harmful to low-entropy join attributes. To address this issue, an intuitive solution is to pad all the occurrences of each (w, w^*) with dummy strings to the maximum volume $L_{max}[i][attr^*]$, which is the biggest occurrence of w^* in Tab_i for each w. Thus, this naı̈ve strategy suffers from a large server storage $cost \ 2mnT + L_{max}mnT.$

To achieve better storage efficiency, our basic idea is to assign each pair ($(w, attr^*, w^*)$,ct) in CSet to XOR filter [15, 37] and then pad the remaining empty locations with dummies. Thus, the total storage overhead is 3.23mnT at the worst case (cf. Section 6.1), where the storage of CSet is reduced from $L_{max}mnT$ to 1.23mnT. Interestingly, sub-query results are obfuscated based on the padding strategy, preventing the server from accessing the exact records matching with any two-table join. Therefore, we can achieve equijoin queries over multiple tables without join pre-computation, while enjoying join over low-entropy attributes with $O(\ell_1)$ query complexity and 3.23mnT storage overhead.

1.3 Related Work

In 2000, Song et al. introduced the notion of symmetric searchable encryption (SSE), which enables the server to perform keyword-based search on encrypted data, while maintaining data and query

¹When the query involves three or more tables, sub-query leakage (SRP) reveals whether some records are present in the join of two tables but not in the multi-table join. SRP is formalized as sub-query result pattern (SRP), as described in Section 5.

privacy. A variety of research progress has been done on enhanced security [5, 6, 8, 13, 26, 38], expressive queries [10, 11, 22, 24, 25, 32], and optimized performance [1, 9, 27, 36, 37]. Although SSE can achieve efficient search over encrypted documents, such as NoSQL databases and cloud storage, it is still challenging to design secure SQL queries over encrypted relational databases.

Hacigümüş et al. [18] firstly explored the study of SQL queries on encrypted relational databases, where each attribute domain is mapped into a series of non-overlapping data buckets and all the items of the corresponding bucket will be returned. Thus, it leads to high communication overhead and leaks the exact range of queried data. Popa et al. [32] presented a practical encrypted relational database system named CryptDB by integrating propertypreserving encryption (PPE), such as deterministic encryption [2] and order-preserving encryption [4, 31]. That is, each column in table will be encrypted with the composition of different types of PPE-encryption schemes (i.e., onion encryption). To perform certain SOL queries, the server decrypts the composition ciphertext by layer until the corresponding layer is reached. However, it has been reported in [16, 29] that PPE-based constructions leak non-trivial information, e.g., data sorting and frequency. Although existing leakage-abuse attacks [3, 17, 23, 30, 33] focus mainly on exact or range queries, Hoover et al. [20] take the first step to explore the SQL-oriented leakage-abuse attacks relying on access pattern, e.g., volume leakage from selections or joins. We note that the above attacks are mitigated effortlessly using volume-hiding technique. Interestingly, our final protocol (JXT++) conceals the volumes of selection and join operations, which is not susceptible to the mentioned attacks. Nevertheless, it is essential to develop SQL queries over encrypted relational databases that reveal as little information as possible.

To design SQL queries with reduced leakage, Kamara et al. [25] presented a novel SQL queries scheme named SPX based on structure encryption, where all possible joins are pre-computed and stored in the encrypted database by heuristic normal form (HNF) representation. Although SPX reveals less leakage than PPE-style construction, it inevitably brings considerable storage blowup due to equi-join computation. Later, Cash et al. [11] introduced the notion of partially pre-computed joins and transferred certain join operations to the client. In addition, Hahn et al. [19] presented a fine-granularly secure join by adopting attribute-based encryption, that reveals only the equality pattern for records matching the selection criterion. Shafieinejad et al. [34] further designed secure equi-join for multiple queries from function-hiding inner product encryption, which leaks only the sum of the leakage of each query. Nevertheless, it suffers from performance bottleneck due to expensive public-key operations.

Recently, Jutla et al. [22] extended the well-known OXT [10] to join queries over two tables, and presented a new join queries scheme dubbed JXT without join pre-computation. More concretely, the server performs single-keyword search for two queried tables separately and checks the existence of all combinations of the matching record identifiers and join-attribute value pairs across tables. However, JXT only supports natural join (i.e., the same name for join attributes) over two tables. Thus, it is imperative to design secure equi-join queries over multiple tables.

2 Preliminaries

In this section, we provide some required primitives throughout this paper, such as encrypted multi-map and Join queries.

2.1 Symmetric Encryption

A symmetric encryption (SE) scheme is composed of three polynomialtime algorithms SE = (Gen, Enc, Dec):

Gen(1^{λ}): On input of security parameter λ , it outputs a secret kev K.

Enc(K, m): On inputs of a secret key K and a message m, it outputs a ciphertext ct.

Dec(K, ct): On inputs a secret key K and a ciphertext ct, it outputs the corresponding message m or an error symbol \perp .

Correctness. A symmetric encryption scheme is computationally correct if for any message m and secret key K, the probability of the corresponding ciphertext ct can be correctly recovered is overwhelming, i.e., Pr[Dec(K, ct) = m] = 1.

Security. Informally, a standard IND-CPA secure SE scheme ensures that an adversary, with access to encryption oracle, cannot distinguish ciphertexts from two messages with the same length.

Definition 2.1. A symmetric encryption scheme SE = (Gen, Enc, Dec) is IND-CPA secure if for all PPT adversaries \mathcal{A} , its advantage

$$Adv_{\text{SE},\mathcal{A}}^{\text{IND-CPA}}(\lambda) = |\Pr[\exp_{\text{SE},\mathcal{A}}^{\text{IND-CPA}}(\lambda) = 1] - 1/2|$$

 $Adv_{\text{SE},\mathcal{A}}^{\text{IND-CPA}}(\lambda) = |\Pr[\mathsf{Exp}_{\text{SE},\mathcal{A}}^{\text{IND-CPA}}(\lambda) = 1] - 1/2|$ is negligible in λ , where the experiment $\mathsf{Exp}_{\text{SE},\mathcal{A}}^{\text{IND-CPA}}(\lambda)$ between a challenger and an adversary \mathcal{A} is defined as follows.

Setup: The challenger generates a key $K \leftarrow \text{Gen}(1^{\lambda})$.

Query 1: The adversary ${\cal A}$ adaptively accesses the encryption oracle, meaning that when A queries on $m \in M$, the challenger returns $ct \leftarrow \text{Enc}(K, m)$.

Challenge: The adversary A sends two messages m_0 and m_1 with the same length to the challenger. Then the challenger generates two ciphertexts $c_0 \leftarrow \operatorname{Enc}(K, m_0)$ and $c_1 \leftarrow \operatorname{Enc}(K, m_1)$ and . After that, the challenger chooses a bit $b \in \{0, 1\}$ randomly and gives c_b to A.

Query 2: The adversary ${\cal A}$ adaptively accesses the encryption oracle again, similar to Phase 1, and subsequently it outputs a bit $b' \in \{0, 1\}.$

Guess: The adversary \mathcal{A} outputs a bit $b' \in \{0, 1\}$. The experiment returns 1 if b' = b and 0 otherwise.

2.2 XOR Filter

Graf and Lemire [15] first introduced the notion of XOR filter, which can be used to achieve membership checking with nearoptimal storage overhead. Later, Wang et al. [37] provided its formal description and applied it to encrypted data search ².

Let \mathcal{U} be the universe of all possible inputs (i.e., strings) and B an array of λ -bit values. As shown in Algorithm 1, a (b, r)-XOR filter XF = (XF.Setup, XF.Update, XF.Query) consists of the following algorithms:

XF.Setup(b, r): It takes as input $b, r \in \mathbb{N}$, and samples a collection of universal hash functions $\mathcal{H} = \{h_t : \mathcal{U} \to [\frac{t}{r}b, \frac{t+1}{r}b)\}$, where

 $^{^2}$ As stated in [37], XOR filter can achieve data retrieving by replacing H(x) with any data y at the corresponding positions $\{h_t(x)\}_{t\in[0,r-1]}$.

Algorithm 1 XOR Filter

```
XF.Setup(b, r)
                                                                                                      4: end for
                                                                                                      5: return R
  1: B \leftarrow \emptyset, where |B| = b
                                                                                                    Mapping Step(\mathcal{H}, S)
  2: H: \mathcal{U} \to \{0,1\}^{\lambda}
  3: \mathcal{H}=\{h_t: \mathcal{U} \to \left[\frac{t}{r}b, \frac{t+1}{r}b\right)\}, where t \in [0, r-1]
                                                                                                      1: Stack, Queue ← Ø
  4: return (H, B)
                                                                                                      2: T \leftarrow \emptyset, where |T| = b
                                                                                                      3: for x ∈ S do
XF.Update(\mathcal{H}, B, S)
                                                                                                               for t = 0 to r - 1 do
  1: Stack \leftarrow Mapping Step(\mathcal{H}, S)
                                                                                                                    T[h_t(x)] \leftarrow T[h_t(x)] \cup \{x\}
  2: for (x, i) \in Stack do
                                                                                                               end for
                                                                                                      6:
          B[i] \leftarrow H(x)

  1: R \leftarrow 0^{\lambda}
                                                                                                               return Failure
                                                                                                     25
  2: for t = 0 to r - 1 do
                                                                                                         end if
                                                                                                     26:
          R \leftarrow R \oplus B[h_t(x)]
                                                                                                     27: return Success and Stack
```

 $t \in [0, r-1]$. Finally, it outputs \mathcal{H} and an initial empty array B of size b.

XF.Update(\mathcal{H}, B, S): It takes as input a family of hash functions \mathcal{H} , an empty array B, and a data set $S \subseteq \mathcal{U}$, then determines the order of inserting all elements by running Mapping Step, and pushes the elements to Stack following the order. For each $(x,i) \in Stack$, it sets $B[i] \leftarrow x \bigoplus_{t \in [0,r-1] \setminus \{t'\}} B[h_t(x)]$, where $h_{t'}(x) = i$, and finally outputs array B.

XF.Query(\mathcal{H}, B, x): It takes as input \mathcal{H}, B as well as an element x, and returns $R = \bigoplus_{t=0}^{r-1} B[h_t(x)]$.

Perfect Completeness. An XOR filter is perfectly complete if for all integers $b, r \in \mathbb{N}$, all element set $S \subseteq \mathcal{U}$, $x \in S$ and $B_S \leftarrow \mathsf{XF.Update}(\mathcal{H}, B, S)$, it holds that $\Pr[\mathsf{XF.Query}(\mathcal{H}, B_S, x) = x] = 1$. This means that any inserted element can always be retrieved.

Parameter Choices. The storage cost of XOR filter is very close to the lower bound O(n) while supporting efficient data query, where n denotes the size of set S. As indicated in [7, 28], the Mapping Step of XOR filter can assign all elements in set S to a set of n = |S| edges generating an acyclic r-partite hypergraph, where the storage overhead is $C_r n + \beta$. The minimal value C_r is about 1.23 when r = 3. Thus, the size of B is $\lfloor 1.23n \rfloor + \beta$.

2.3 Encrypted Multi-Map

We recall multi-map, an abstract data structure for data retrieving is formalized in [14, 26]. Specifically, multi-map enables to store key/value pairs MM = $\{(k, \vec{v}_k)\}$. Here, we denote by MM[k] all values associated with key k. A multi-map supports the following operations:

 $\operatorname{Get}(k)$: On input of a key k, it outputs the associated tuple $\vec{v}_k = \operatorname{\mathsf{MM}}[k]$.

Put (k, \vec{v}_k) : On input of a key/value pair (k, \vec{v}_k) and inserts it into multi-map, i.e., $\mathsf{MM}[k] = \vec{v}_k$.

To design encrypted search protocol, we further recall the notion of encrypted multi-map (EMM). Specifically, the syntax of response-hiding EMM [24] EMM = (Setup, Search, Reslove) is presented as follows:

Setup(1^{λ} , MM): The client takes a security parameter λ and a multi-map MM as input, and outputs a secret key K and an encrypted multi-map EMM.

Search(K, q; EMM): The client takes secret key K as well as a query q as input and sends the corresponding search token tk_q to the server. Then the server performs search on EMM with tk_q . Finally, the server sends the encrypted search result EMM[q] to the client.

Resolve(K, EMM[q]): The client takes as input a secret key K and an encrypted search result EMM[q], and outputs a response MM[q].

Generally, EMM can be classified into response-revealing and response-hiding. The former reveals the response to queries in plaintext, whereas the latter requires the client to decrypt the retrieved results locally. A response-revealing EMM scheme can be achieved by having Search algorithm output the response in plaintext directly and omitting Resolve algorithm.

Correctness. An encrypted multi-map scheme Σ is computationally correct if any adversary \mathcal{A} has a negligible probability of winning the following game $\operatorname{Cor}_{\mathcal{A}}^{\Sigma}$. The adversary selects a multi-map MM and obtains EMM via Setup(1^{λ} , MM). The adversary then non-adaptively chooses a list of queries \mathbf{q} , and the game runs Search(K, $\mathbf{q}[i]$; EMM) and returns all encrypted search results EMM[$\mathbf{q}[i]$] for all $i \in [|\mathbf{q}|]$. If any output by Resolve(K, EMM[$\mathbf{q}[i]$]) is not equal to the corresponding MM[$\mathbf{q}[i]$] ($i \in [|\mathbf{q}|]$), the game outputs 1; otherwise, it outputs 0. Σ is computationally correct if $\operatorname{Pr}[\operatorname{Cor}_{\mathcal{A}}^{\Sigma}(\lambda) = 1] \leq \operatorname{negl}(\lambda)$ for all \mathcal{A} .

Security. We define the non-adaptive security of an encrypted multi-map scheme using a leakage function \mathcal{L} , which represents the information revealed to an adversary during real-world scheme. Essentially, the scheme ensures that the adversary \mathcal{A} cannot gain more information beyond what \mathcal{L} reveals.

Definition 2.2 (Non-adaptive Security of Encrypted Multi-map). Let $\Sigma = (\text{Setup}, \text{Search})$ be an encrypted MM and $\mathcal L$ be its leakage function. We say Σ is $\mathcal L$ -semantically secure against non-adaptive attacks if for all PPT adversaries $\mathcal A$, there exists an efficient simulator $\mathcal S$ such that

$$\left|\Pr[\mathbf{Real}_{\mathcal{A}}^{\Sigma}(\lambda) = 1] - \Pr[\mathbf{Ideal}_{\mathcal{A},\mathcal{S}}^{\Sigma}(\lambda) = 1]\right| \leq \mathsf{negl}(\lambda)$$

where $\mathbf{Real}^\Sigma_{\mathcal{A}}(\lambda)$ and $\mathbf{Ideal}^\Sigma_{\mathcal{A},\mathcal{S}}(\lambda)$ are defined as follows:

 $\mathbf{Real}_{\mathcal{A}}^{\Sigma}(\lambda)$: \mathcal{A} chooses a multi-map MM and a list of queries \mathbf{q} . The experiment runs $\mathrm{Setup}(1^{\lambda}, \mathrm{MM})$ and returns EMM to \mathcal{A} . For each $i \in [|\mathbf{q}|]$, the experiment runs $\mathrm{Search}(K, \mathbf{q}[i]; \mathrm{EMM})$, and returns the transcript and client's output to \mathcal{A} . Finally, \mathcal{A} outputs a bit b as the output of this experiment.

Ideal $_{\mathcal{A},\mathcal{S}}^{\Sigma}(\lambda)$: \mathcal{A} chooses a multi-map MM and a list of queries \mathbf{q} . The experiment runs $\mathcal{S}(\mathcal{L}(\mathsf{MM},\mathbf{q}))$ and returns its outputs to \mathcal{A} . Finally, \mathcal{A} outputs a bit b as the output of this experiment.

To facilitate the description of our protocols, we further introduce TSet [10, 22], which essentially serves as a response-revealing EMM. It maintains a collection of fixed-size values indexed by keys, which can be subsequently accessed through key-based tokens. Formally, a TSet instantiation is defined by three polynomial-time algorithms, described as follows:

TSetSetup(1^λ, T): It takes as input a security parameter λ and a multi-map T = $\{(k, (v_k[1], \ldots, v_k[|\mathsf{T}[k]|]))\}_{k \in \mathbb{K}}$, where \mathbb{K} is the set of keys in T, with each key $k \in \mathbb{K}$ having a corresponding list of values of equal bit length, i.e., $v_k[1], \ldots, v_k[|\mathsf{T}[k]|]$. It then outputs a secret key K_T and an EMM TSet.

TSetGetTag(K_T , k): It takes as input the secret key K_T and a queried key k, then outputs a search token stag.

TSetRetrieve(TSet, stag): It takes as input TSet and stag associated to k, and finally outputs T[k].

Note that TSet is a specialized type of EMM, and its correctness and security definitions are closely similar to those of EMM. Thus, we omit the details.

2.4 Join Queries over Encrypted Database

We recall the syntax of join queries over encrypted relational database presented in [22]. A relational database DB = $\{\text{Tab}_i, W_i\}_{i \in [N]}$ consists of a set of tables Tab_i , where W_i denotes all attribute-value pairs in Tab_i . For simplicity, assume that Tab_i has m_i rows (i.e., records) and n_i columns (i.e., attributes), Tab_i can be depicted as $\{(\text{ind}_r, \{w_c\}_{c \in [n]})\}_{r \in [m]}$, where $\text{ind}_r \in \{0, 1\}^\lambda$ serves as the record identifier, and $w_c \in \{0, 1\}^*$ denotes the attribute-value pair. Note that ind_r is used to retrieve the corresponding record in outsourced encrypted database. We present some critical notations for join queries across tables as follows:

Record Identifiers: A record identifier, denoted as ind, is a unique value assigned to each record within a table Tab_i in a relational database. The identifier can be disclosed to the server that stores the relational database, enabling it to swiftly retrieve the corresponding encrypted record and send it to the client. We suppose that each record identifier in a table Tab_i is attached to the table number i throughout the paper. That is, there is no identical record identifier in two distinct tables.

Join Attributes: Consider a table ${\sf Tab}_i$ with a total of n attributes, among which T special attribute are designated as "join attributes" denoted by $\{attr_t^*\}_{t\in [T]}$. These join attributes with the size upperbounded are chosen at setup and are used for join queries across tables

Inverted Index: For each attribute-value pair $w \in W_i$, $DB_{\mathsf{Tab}_i}(w)$ refers to the set of identifiers of records matching w, specifically:

$$DB_{Tab_i}(w) = \{ \text{ind } | (\text{ind}, w) \in Tab_i \}.$$

The collection $\{\mathsf{DB}_{\mathsf{Tab}_i}(w)\}_{w\in \mathsf{W}_i}$ is named "inverted index" of the table Tab_i .

Inverted Join Index: For each attribute-value pair $w \in W_i$, $DB_{\mathsf{Tab}_i}^{\mathsf{Join}}(w)$ denotes the set of identifiers of records satisfying w, along with all the pairs of join-attribute/value in the same record. The formal description is as follows:

$$\begin{split} \mathsf{DB}^{\mathsf{Join}}_{\mathsf{Tab}_i}(w) &= \left\{ (\mathsf{ind}, \{attr_t^*, w_t^*\}_{t \in [T]}) \mid \right. \\ & \left. (\mathsf{ind}, w) \in \mathsf{Tab}_i \land \forall t \in [T], (\mathsf{ind}, attr_t^*, w_t^*) \in \mathsf{Tab}_i \right\}. \end{split}$$

All the $\{DB_{Tab_i}^{Join}(w)\}_{w \in W_i}$ is called as "inverted join index" of table Tab_i.

Join Query: A join query over k tables $\mathsf{Tab}_{t_1},...,\mathsf{Tab}_{t_k}$ with corresponding attribute-value pair sets $\mathsf{W}_{t_1},...,\mathsf{W}_{t_k}$, respectively, is specified by a tuple

$$q = (\{t_1, ..., t_k\}, \{w_1, ..., w_k\}, \{attr_{t_1}^*, ..., attr_{t_k}^*\})$$

where $w_i \in W_{t_i}$, and $attr_{t_i}$ is a join attribute of table Tab_{t_i} which defines the join relation across the tables for the query q.

We write $\mathsf{DB}(q)$ to be the collection of tuples of the form $(\mathsf{ind}_{t_1}, ..., \mathsf{ind}_{t_k})$ that satisfy the query q. Each tuple consists of k record lists corresponding to k queried table, and records in a tuple share the

common join-attribute value. Formally, for each $(\mathbf{ind}_{t_1},...,\mathbf{ind}_{t_k}) \in \mathsf{DB}(q)$, this means that the following conditions hold simultaneously:

$$\bigcap_{i=1}^k (\mathbf{ind}_{t_i}, w_i) \in \mathsf{Tab}_{t_i}, \ \exists \gamma \ \mathsf{s.t.} \bigcap_{i=1}^k (\mathbf{ind}_{t_i}, \langle \mathit{attr}_{t_i}, \gamma \rangle) \in \mathsf{Tab}_{t_i}$$

3 Equi-Join Queries over Two Tables

In this section, we present JXT+, a new equi-join query scheme over two tables without join pre-computation, which enjoys better query and storage efficiency than the state-of-the-art JXT [22].

Assume that $F:\{0,1\}^{\lambda}\times\{0,1\}^*\to\{0,1\}^{\lambda}$ is pseudorandom function, SE = (Gen, Enc, Dec) is IND-CPA secure symmetric encryption scheme, TSet = (TSetSetup, TSetGetTag, TSetRetrieve) is a non-interactive response-revealing EMM, and CSet is a multimap. Our construction is comprised of one algorithm EDBSetup and one protocol Search in Algorithm 8 and the details of JXT+ are shown as follows:

EDBSetup(1^{λ} , DB): The client first randomly picks secret keys K_z , K_w , K_r , $K_{\rm enc} \in \{0,1\}^{\lambda}$ for PRF F, and parses database DB as ${\mathsf{Tab}}_i, {\mathsf{W}}_i\}_{i\in[N]}$, where ${\mathsf{W}}_i$ denotes the set of all attribute-value pairs in table Tab_i. Then the client initializes an empty array T_i , an empty set XSet[i] and an empty multi-map CSet[i] for each table Tab_i. After that, the client inserts each pair $(w, DB_{Tab_i}^{Join}(w))$ of Tabi into encrypted database EDB (cf. line 5-21). More concretely, for each pair of $(w, attr_t^*)$, the client first computes all the values $\{F(K_w, w_t^*) \oplus F(K_z, w||\text{cnt})\}$ and stores them at location $T_i[w||attr_t^*]$, which can be used to determine the number of record matching with w. Then, all $\{xtag\}$ for each tuple $(w, w_t^*, attr_t^*)$ are inserted into XSet[i], which is the key component to achieve efficient eugi-join across two tables. Moreover, an additional data structure CSet[i] is used to store all pairs (xtag, ct). Finally, it outputs the secret key $K = (K_z, K_w, K_r, K_T, K_{enc})$ and encrypted database EDB = (TSet, XSet, CSet).

Algorithm 3 Equi-join Queries over Multiple tables (JXT++)

```

Search(K, q; EDB): To perform equi-join query q over Tab_{t_1} and Tab_{t_2} , the client sends stag for pair $(w_1, attr_{t_1}^*)^3$ and table indices $\{t_1, t_2\}$, along with xjointoken₁ and xjointoken₂ arrays until instructed by the server to stop ⁴. Next, the server retrieves the corresponding values $\mathsf{T}_{t_1}[w_1||attr_{t_1}^*]$ by calling TSetRetrieve and filters out the final result by checking whether the combination of $(w_1^*, w_2, attr_2^*)$ is in XSet. Specifically, the server computes xtoken₂ = xjointoken₂[i] $\oplus y_i$ for each value in $\mathsf{T}_{t_1}[w_1||attr_{t_1}^*]$ and tests whether xtoken₂ \in XSet. If hold, the server returns the matching encrypted

identifiers CT associated with xtoken₁ and xtoken₂, where xtoken₁ = xjointoken₁ [i] \oplus y_i .

Remark 1. Here, we briefly present a variant of JXT+, named FJXT+, which enables to retrieve all rows matching attr $_{t_1}^*$ = attr $_{t_2}^*$ without giving specific attribute-value pairs w_1 and w_2 . Specifically, to achieve full equi-join without a filter, the only required change for FJXT+ is to insert an extra attribute column attr $_0^i$ for each table Tab_i filled with merely "#" at setup phase. When performing query $q = (\{t_1, t_2\}, \{w_1 = attr_0^1 | | \#, w_2 = attr_0^2 | | \# \}, \{attr_{t_1}^*, attr_{t_2}^* \})$, the client generates stag for pair $(w_1, attr_{t_1}^*)$, and the server can retrieve all rows (i.e., records) matching attr $_{t_1}^*$ from TSet, then the server can check if the retrieved TSet entries satisfy the join query (cf. line 12-24).

 $^{^3}$ It is unnecessary to reveal the join-attribute to the server in our protocol, while it will leak to the server for determining the desirable entry in JXT.

 $^{^4}$ JXT+ has only a single round of interaction similar as OXT and JXT, and its communication cost is composed of $(\{t_1, t_2\}, \text{stag}, \{(\text{xjointoken}_1[1], \text{xjointoken}_2[1]), \dots, (\text{xjointoken}_1[\text{cnt}], \text{xjointoken}_2[\text{cnt}])\})$.

To reflect the influence of change, we give a theoretical analysis of FJXT+ in terms of storage and query efficiency. For simplicity, assume that each table has m records and n attributes, with T join-attribute. Similar to JXT+, the total storage size of FJXT+ is 3m(n+1)T in the worst case due to the insertion of an additional attribute column. For query overhead, the client generates a token for the pair of $(w_1 = attr_0^1|\#, attr_{t_1}^*)$ and retrieves all the m rows (i.e., no filtering), then generates 2m cross-tokens xjointoken. Thus, the computation complexity for token generation is O(m)Prf. In addition, to retrieve all rows (m) in Tab_{t_1} , the server needs to perform O(m) Prf and O(m) XOR operations for join with $attr_2^*$. Then the server and the client are required to compute O(|R|) hash and O(|R|) decryption operations, respectively. Overall, the query overhead is O(m)Prf + O(|R|)Dec for the client and O(m)(Prf + Xor) + O(|R|)H for the server.

4 Equi-Join Queries over Multiple Tables

In this section, we propose JXT++, the first equi-join query scheme over multiple tables without pre-computation, by extending our basic scheme JXT+, which can support join of arbitrary low-entropy attributes and mitigate the sub-query leakage.

Let $F:\{0,1\}^{\lambda}\times\{0,1\}^*\to\{0,1\}^{\lambda}$ be a PRF, SE = (Gen, Enc, Dec) an IND-CPA secure SE scheme, and $\Sigma=$ (TSetSetup, TSetGetTag, TSetRetrieve) a non-interactive response-revealing EMM. Given any database DB = $\{\mathsf{Tab}_i, \mathsf{W}_i\}_{i\in[N]}$, the client initializes a two-dimensional array L_{max} with size $N\times T$ to store the maximum occurrence number of each pair $(w,w_t^*)_{w\in \mathsf{W}_i,t\in[T]}$, where w_t^* is the corresponding value of join attribute $attr_t^*$ in table Tab_i. JXT++ consists of one algorithm EDBSetup and one protocol Search in Algorithm 3 and the details are described as follows:

EDBSetup(1^{λ} , DB): The client first parses the database DB as $\{Tab_i, W_i\}_{i \in [N]}$, and randomly picks keys $K_z, K_{z'}, K_r, K_w, K_c, K_{enc} \in$ $\{0,1\}^{\lambda}$ for PRF F. Then it initializes T_i as an empty array, XSet[i]as an empty set, and M as an empty map for each table Tab_i. Later, the client inserts all the pairs $(w, \mathsf{DB}^{\mathsf{Join}}_{\mathsf{Tab}_i}(w))$ of Tab_i into EDB (cf. line 4-26). Specifically, the client computes all values $F(K_z, w_t^*) \oplus F(K_z, w)$ and appends into $T_i[w||attr_t^*]$ for each pair of $(w, attr_t^*)$. The client further computes xtag = $F(K_r, attr_t^*) \oplus$ $F(K_w, w_t^*) \oplus Z' \oplus F(K_c, 1)$ for $(w, w_t^*, attr_t^*)$ and stores all $\{xtag\}$ into XSet[i]. In addition, each encrypted identifier ct is stored into map **M** indexing by a unique token (i.e., xtag = $F(K_r, attr_t^*) \oplus$ $F(K_w, w_t^*) \oplus Z' \oplus F(K_c, \text{cnt})$. After that, all pairs (xtag, ct) in **M** is used to generate array CSet[i] by invoking XF.Update, which can hide the frequency of pair (w, w_t^*) . Finally, it outputs the secret key K = $(K_z, K_{z'}, K_r, K_w, K_c, K_{enc})$ and encrypted database EDB = (TSet, XSet, CSet).

Search(K, q; EDB): To perform equi-join over k tables, the client sends stag for pair $(w_1, attr_{t_1}^*)$, queried table indices $\{t_1, \ldots, t_k\}$, and xjointoken array to the server. Then, the server first retrieves all values $\mathsf{T}_{t_1}[w_1||attr_{t_1}^*]$ by invoking TSetRetrieve. Next, the server generates k-1 tokens for each retrieved value y_{cnt} (i.e., $\{\mathsf{xtoken}[i][1] = \mathsf{xjointoken}[i][1] \oplus y_{\mathrm{cnt}}\}_{i \in [2,k]}$), which is used to determine whether it is in the join of Tab_{t_1} and Tab_{t_i} . After all checkings are successful, it computes $\mathsf{xtoken}[j][c] = \mathsf{xjointoken}[j][c] \oplus y_{\mathrm{cnt}}$ and retrieves the corresponding ciphertext of record identifier $\mathsf{ct}_j[c]$ by

invoking XF.Search (cf. line 20-28). Finally, it returns all ciphertexts $\{(\mathbf{ct}_1, \dots, \mathbf{ct}_k)\}$ to the client.

5 Security Analysis

Assume that a database DB = $\{\text{Tab}_i, W_i\}_{i \in [N]}$ consists of N tables, and each Tab_i has m_i rows and n_i columns. We define a sequence of Q queries as \mathbf{q} , where the i-th query, for $1 \leq i \leq Q$, is represented as $\mathbf{q}[i] = (\{\mathbf{t}_1[i], \ldots, \mathbf{t}_k[i]\}, \{\mathbf{w}_1[i], \ldots, \mathbf{w}_k[i]\}, \{\mathbf{attr}_{\mathbf{t}_i}^*[i], \ldots, \mathbf{attr}_{\mathbf{t}_k}^*[i]\})$. Then the leakage function $\mathcal{L}_{JXT+} = (\mathsf{n}, \mathsf{RP}, \mathsf{EP}, \mathsf{JD})$ for JXT+ are defined as follows:

- n is the *size pattern of tables*, representing the size of each table in DB. Formally, $n[i] = m_i n_i$ for $i \in [N]$.
- RP is the *result pattern*, which is the set of records matching each query. Formally, RP[i] = DB(q[i]), i ∈ [Q].
- EP is the *equality pattern* indicating which queries have equal combination of $w_1[i]||attr_{t_1}^*[i]$. Formally, we represent EP as an integer vector and each integer refers to a unique combination. That is, EP[i] = EP[j] if $(w_1[i]||attr_{t_1}^*[i]) = (w_1[j]||attr_{t_1}^*[j])$ for $i, j \in [Q]$.
- SP is the *size pattern* of the queries, which indicates the number of records matching $w_1[i]||attr_{t_1}^*[i]$ in TSet. Formally, $SP[i] = |T_{t_1[i]}(w_1[i]||attr_{t_1}^*[i])|$ for $i \in [Q]$.
- JD is the *join-attribute distribution pattern*, which mainly leaks the join-attribute values corresponding to the combination of attribute-value pair $w_1[i]$ and join attribute $attr_{t_1}^*[i]$ in the table $Tab_{t_1[i]}$. More formally, for each $i \in [Q]$, we denote JD[i] as a multi-set

$$JD[i] = \{encode(val^*) : (ind, w_1[i]) \in Tab_{t_1[i]}$$

$$\land (ind, \langle attr_{t_1}^*[i], val^* \rangle) \in Tab_{t_1[i]} \}.$$

Before presenting the formal security analysis of our schemes, we first recall the conditional intersection pattern (IP) leakage in [22] considering query on two tables, and introduce the sub-query result pattern (SRP) leakage.

• IP is the *conditional intersection pattern* which is a $Q \times Q$ table. Specifically, for each $i, j \in [Q]$, IP[i, j] is empty if one of the following conditions holds:

$$- \ (t_1[i], t_2[i], attr^*_{t_1}[i], attr^*_{t_2}[i]) \neq \\ (t_1[j], t_2[j], attr^*_{t_1}[j], attr^*_{t_2}[j]).$$

 $- JD[i] \cap JD[j] = \emptyset.$

Otherwise, IP[i, j] is defined as the intersection of all record identifiers matching the attribute-value pair $w_2[i]$ and $w_2[j]$ in the table $Tab_{t,\lceil i\rceil}$. More formally, we have

$$\mathsf{IP}[i,j] = \mathsf{DB}_{\mathsf{Tab}_{t_2[i]}}(w_2[i]) \cap \mathsf{DB}_{\mathsf{Tab}_{t_2[i]}}(w_2[j]).$$

• SRP is the *sub-query result pattern*, which is represented as a collection of $Q \times (k-1)$ sets. Formally, for $i \in [Q]$, we first divide q[i] into (k-1) sub-queries, that is, for $j \in [k-1]$,

$$\mathbf{q}_{j}[i] = (\{t_{1}[i], t_{j+1}[i]\}, \{w_{1}[i], w_{j+1}[i]\}, \{attr_{t_{i}}^{*}[i], attr_{t_{i+1}}^{*}[i]\}).$$

Then SRP[i][j] is the search result for the j-th sub-query $q_j[i]$. More formally, for $i \in [Q]$ and $j \in [k-1]$, we have $SRP[i][j] = DB(q_j[i])$.

Leakage Comparison on Equi-join without Pre-computation: Similar to JXT, our proposed schemes JXT+ and JXT++ can support leakage comparison of the three schemes, as shown in Table 2. Note

join queries without join pre-computation. So, we provide a detailed that JXT and JXT+ support join query on two tables, while JXT++ works on multiple tables. In the following, we give the details:

All three schemes have the leakage of size pattern n, which comes from the size of TSet. The equality pattern EP can be derived from the repetition of the stags when performing search for the same attribute-value pair w and $attr^*$. Specifically, in JXT, the client generates stag⁽¹⁾ and stag⁽²⁾ for the queried attribute-value pair w_1 of Tab_{t_1} and w_2 of Tab_{t_2} , respectively. Thus JXT leaks the equality pattern of Tab_{t_1} and Tab_{t_2} , being denoted as EP_1 and EP_2 . The server in JXT proceeds to retrieve the search results for w_1 and w_2 based on $stag^{(1)}$ and $stag^{(2)}$, obviously leaking the size patterns SP_1 and SP_2 for w_1 and w_2 , respectively. In contrast, JXT+ and JXT++ leak EP1 but not EP2 since the client only produces the stag for $w_1||attr_{t_1}^*$, and then the server retrieves the matching TSet entries for $w_1||attr_{t_1}^*$. Note that in JXT+, the server can retrieve all records matching $w_1||attr_{t_1}^*$, whereas in JXT++, the server only retrieves one copy of records with the same $(w_1||attr_{t_1}^* = w^*)$. Therefore, JXT+ has SP₁ leakage, while JXT++ does not.

In the following, we first analyze the subtle leakage JD which reflects the frequency distribution of join-attribute values w* corresponding to the join attribute $attr_{t_1}^*[i]$ in the records matching the attribute value pair $w_1[i]$. In JXT and JXT+, this leakage comes from the fact that for the records share the same w^* in the *i*-th query (or the records in the *i*-th and *j*-th queries), the server gets the same value of xtag for checking whether $(w^*, w_2[i])$ is in the XSet (if the records in different queries, this hold with a condition of $(w_2[i]||attr_{t_2}^*[i]) = (w_2[j]||attr_{t_2}^*[j])$). In contrast, JXT++ does not leak the JD when considering a single query (e.g. the i-th query), since JXT++ stores only one copy of records with the same $(w_1[i]||attr_{t_1}^*[i] = w^*)$. However, we note that JXT++ leaks the JD in different queries for reasons similar to those in JXT and JXT+.

JXT+ and JXT++ eliminate the IP leakage that is present in JXT. Recall that IP leakage reveals the intersection of records matching the attribute-value pairs w_2 in the Tab_{t_2} in different queries with the condition that there exists two records from different queries matching w_1 have identical w^* . This leakage comes from the fact that the xtag is the encrypted version of the pair (w^*, ind) in JXT. That is, given a specific w^* , the server can get the identical xtag if two queries share the same *ind*. For clarity, we take an example to illustrate. For the *i*-th and *j*-th query, assume that there is one record matching $w_1[i]$ and another record matching $w_1[j]$ have a common w^* . In this case, if the server learns the xtags for *indi* from the results of $w_2[i]$ and ind_j from the results of $w_2[j]$ are identical, then $ind_i = ind_i$. In contrast, JXT+ and JXT++ remove the IP leakage since the xtag is the encrypted version of the pair (w^*, w_2) . Therefore, the server cannot get the identical value even when a record *ind* matches both $w_2[i]$ and $w_2[j]$.

SRP is a straightforward leakage for multi-table queries. Specifically, the idea of performing multi-table queries is that the server first retrieves the results from Tab_{t_1} , and then filters the results that satisfy the sub-queries for $\mathsf{Tab}_{t_2}, \cdots, \mathsf{Tab}_{t_k}$ individually. Consequently, it naturally reveals the results matching Tab_{t_1} and Tab_{t_i}

Table 2: Leakage comparison with JXT.

Scheme	n	RP	EP ₁	EP_2	SP ₁	SP ₂	JD	IP	SRP
JXT [22]	•	•	•	•	•	•	•	•	_
JXT+	•	•	•	•	•	0	•	0	_
JXT++	•	0	•	•	0	0	•	0	0

The symbols \bullet , \bullet , and \bigcirc denote fully, partially, and without revealing the leakage.

for $2 \le i \le k$. However, we note that the search results in JXT++ contain some dummy values for each sub-query, thus it does not have the SRP leakage.

Theorem 1. Our JXT+ protocol is \mathcal{L} -semantically-secure against non-adaptive attacks where the leakage function $\mathcal{L} = (\mathcal{L}_{IXT+}(DB, \mathbf{q}),$ $\mathcal{L}_{\mathsf{T}}(\mathsf{DB}, \mathsf{t}_1, \mathsf{w}_1, \mathsf{attr}_1^*)$, assuming that F is a secure PRF, SE is a standard IND-CPA secure symmetric encryption scheme, and TSet is a non-adaptively \mathcal{L}_T -secure instantiation.

Theorem 2. Our 7XT++ protocol is \mathcal{L} -semantically-secure against non-adaptive attacks where the leakage function $\mathcal{L} = (\mathcal{L}_{IXT++}(DB, \mathbf{q}),$ $\mathcal{L}_{\mathsf{T}}(\mathsf{DB}, \mathsf{t}_1, \mathsf{w}_1, \mathsf{attr}_1^*)$, assuming that F is a secure PRF, SE is a standard IND-CPA secure symmetric encryption scheme, and TSet is a non-adaptively \mathcal{L}_{T} -secure instantiation.

The proof of Theorem 1 is provided in Appendixes A. The proof of Theorem 2 is similar to that of Theorem 1 and is omitted here. We remark that both of our protocols are also secure against adaptive attacks. Here, the adaptive security proof is essentially an extension of the non-adaptive proof. In brief, the key difference is that the adaptive security proof involves using the adaptive TSet simulator, XSet and CSet are be simulated to adaptively respond to the adversary's queries. Note that the proofs of adaptive security for our protocols are also similar to those of [22], so we omit the details.

Performance Evaluation

In this section, we provide a detailed asymptotic comparison between our proposed schemes and the most related works. We then describe the implementation configuration and present the detailed experimental results.

6.1 Theoretical Comparison

In the following, we present a performance comparison of JXT+ and JXT++ with SPX [25], CNR [11] and JXT [22] in terms of query and storage efficiency. For simplicity, we consider a database including two tables, Tab₁, Tab₂, each with m rows, n columns, and T join attributes, and suppose the query q = (Select inds FromTab₁, Tab₂ Join On $attr_1^* = attr_2^*$ Where $w_1 \wedge w_2$). A summary of the comparison is given in Table 1.

Storage Overhead. We first focus on the storage size of SPX, CNR, JXT, JXT+ and JXT++. Note that the storage of JXT and our schemes is considered table-wise. Specifically, SPX produces three encrypted multi-maps EMM_R , EMM_C , EMM_V and an encrypted dictionary EDX. EMM_R is a row-wise representation of the database that maps the row's identifier to all the encrypted entities in that row. Similarly, EMM_C is a column-wise representation of the database that maps the column's identifier to the encrypted entities in that column. EMM_V maps each value in a column to the rows' identifiers containing that value. In other words, each of the three encrypted multi-maps encrypts every cell in a table, requiring O(mn) storage. EDX consists of a set of multi-maps, and each includes the

pre-computation of all the join results for a join attribute. Thus, the size of EDX depends on the number of join attributes and the number of rows satisfying the join. In the best case, no results are satisfying the join, then EDX will be empty; while in the worst case, each join-attribute shares the common value in two tables, then the size of EDX is $O(m^2T)$. In summary, the storage size of SPX is $O(mn) + O(m^2T)$.

CNR generates an encrypted multi-map EM and a filter HS of a set SET. EM is similar to EMM $_V$ in SPX that maps each value in every column to the row's identifiers containing that value, thus it requires O(mn) storage. In contrast to EDX in SPX, SET in CNR contains the pre-computation of join rows from each table separately to reduce the storage size. When the join attributes share a common value (i.e., worst case), then the size of SET is O(mT). Hence, the overall storage size of CNR is O(mn) + O(mT).

JXT generates an encrypted multi-map TSet and a set XSet. Specifically, for each attribute-value pair w in the database, TSet stores the encrypted record identifiers, the T combinations of record identifier and join attribute, as well as the T combinations of join-attribute value and attribute-value pair, denoted as $(ct, \{y_t, y_t'\}_{t \in [T]})$. This results in a storage overhead of (2T+1)mn. XSet stores all the combinations of record identifiers and corresponding join-attribute value pairs in the database, having mT storage size. Therefore, the total storage size of JXT is (2T+1)mn+mT.

JXT+ produces an encrypted multi-maps TSet, a set XSet and a multi-map CSet. For every attribute-value pair w and join attribute $attr_t^*$, TSet encrypts the pair of the attribute-value pair and corresponding join-attribute value for the join-attribute name (e.g., (w, w_t^*)). Hence the storage size of TSet is mnT. For each attributevalue pair w, XSet stores combinations of join-attribute name, joinattribute value, and attribute-value pair (e.g., $(attr^*, w^*, w)$). Note that only one copy is stored for the duplicated $(attr^*, w^*, w)$ in XSet. Specifically, it has a storage size of $\sum_{i \in [n], j \in [T]} m_{i,j}^-$, where $m_{i,i}^-$ denotes the number of distinct $(attr^*, w^*, w)$ for the *i*-th attribute column and the j-th join-attribute column. The corresponding sizes are *mnT* and *nT* for the worst and best cases, respectively. CSet is used to store all encrypted record identifiers indexed by $(attr^*, w^*, w)$ and has a storage size of mnT. Overall the total storage sizes of JXT+ are 3mnT and 2mnT+nT for the worst and best cases, respectively.

Similar to JXT+, JXT++ produces an encrypted multi-map TSet, a set XSet and a map CSet. To hide the frequency of join-attribute values, both TSet and XSet in JXT++ will save a single copy for the duplicated ($attr^*$, w^* , w). Besides, the CSet with size of mnT is mapped to an XOR filter by padding dummy values for removing SRP leakage. This results in 1.23mnT storage overhead. Therefore, the total storage sizes of JXT++ are 3.23mnT and 1.23mnT+2nT for worst and best cases, respectively.

Search Efficiency. Next, we proceed to examine the efficiency of performing a query $q = (\text{Select } inds \text{ From Tab}_1, \text{Tab}_2 \text{ Join On } attr_1^* = attr_2^* \text{ Where } w_1 \wedge w_2).$ During the search phase, the computational costs are divided between the client and the server. In detail, the client generates the search token and the server performs search to retrieve the search results and finally the client decrypts them.

In SPX, the client generates tokens for w_1 , w_2 and $attr_1^* = attr_2^*$ respectively, resulting in O(1)Prf. Then the server queries EMM_V

based on the tokens of w_1 and w_2 to recover ℓ_1 and ℓ_2 records; and queries EDX based on the tokens of $attr_1^* = attr_2^*$ to recover $|R_J|$ records, where $|R_J|$ is the number of records satisfying join query $attr_1^* = attr_2^*$; and performs intersection of the results to obtain the final encrypted results R. The decryption of R is performed on the client side. Thus, the query computation cost is $O(\ell_1 + \ell_2 + |R_J|) \text{EMM}_{qry}$ (server side) and O(1) Prf + O(|R|) Dec (client side), respectively.

To reduce storage size, CNR introduces the technique of partially pre-computed joins at the cost of additional client-side computation. That is, the client requires constant PRF to generate the search token of $(w_1, w_2, attr_1^*, attr_2^*)$. On receiving the search token, the server first retrieves the matching records $(\ell_1 \text{ and } \ell_2)$ from encrypted multimap EM with $O(\ell_1 + \ell_2)$ EMM_{qry} computation cost, and then checks whether each result of w_1 (resp. w_2) joins with some value of $attr_2^*$ (resp. $attr_1^*$) based on the filter HS by $O(\ell_1 + \ell_2)$ Prf operation. Therefore, the server computational cost is $O(\ell_1 + \ell_2)$ (EMM_{qry} + Prf) in total. Note that the client needs to decrypt the search result and perform join locally, so the search cost is $O(\ell_1 + \ell_2)Dec + O(\ell_1\ell_2)Join$.

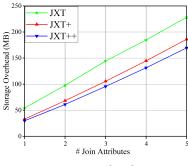

Both of the mentioned schemes involve (full or partial) join precomputation and lead to either high storage size or heavy client computational cost. In contrast, JXT, JXT+, and JXT++ construct table-wise index structures with joinable attributes, avoiding prohibitive join pre-computation. More concretely, the client in JXT generates search tokens for w_1 and w_2 and computes $\ell_1 + \ell_2$ cross-tokens xjointoken, incurring a cost of $O(\ell_1 + \ell_2)Prf$. On the server side, it retrieves ℓ_1 and ℓ_2 encrypted identifiers matching with w_1 and w_2 , respectively, and then performs join with all possible combinations. Thus, the total search cost is $O(\ell_1 + \ell_2)EMM_{qry} + O(\ell_1\ell_2)Xor$. The decryption of identifiers is performed by the client and the entire cost is $O(\ell_1 + \ell_2)Prf + O(|R|)Dec$.

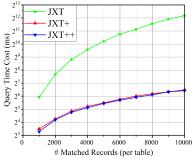

To further reduce join cost, JXT+ stores all combinations of attribute-value pair and join-attribute value (e.g., (w_1, w_1^*)) in each table and achieves the join by checking the combination of $(w_1^*, w_2, attr_2^*)$ in XSet. Specifically, it spends $O(\ell_1) \text{EMM}_{qry}$ to retrieve the records matching $w_1 || attr_1^*$, an additional $O(\ell_1) Xor$ to perform join with $(w_2, attr_2^*)$, and O(|R|)H to retrieve the matched encrypted identifiers ct. The total query cost for server is $O(\ell_1) (\text{EMM}_{qry} + Xor + O(|R|)H)$, where O(|R|)H. In terms of client, the cost consists of token generation for pair $(w_1, attr_1^*)$ and decryption on R search result. i.e., $O(\ell_1) Prf + O(|R|) Dec$.

JXT++ is derived from JXT+ to handle multiple tables. To hide the real number of occurrences of (w, w^*) , all the occurrences of each pair of (w, w^*) are to pad with dummy strings to the maximum volume l_{max} . This results in $O(\ell_1) \mathsf{EMM}_{qry} + O(\ell_1 l_{max})(Xor + H)$ in the worst case (Assuming that all l_1 records satisfying the query q) cost due to the retrieving of dummy data. While the client needs to generate tokens for pair $(w_1, attr_1^*)$, compute cross-tokens xjointoken, and decrypt all the result. Its computation cost is $O(l_{max})Prf + O(\ell_1 l_{max})Dec$.

6.2 Implementation Configuration

We implement our schemes and JXT [22] by using JAVA, employing the JDK library for cryptographic operations like AES and SHA-256. In our experiments, we adopt such a database consisting of 6 tables,

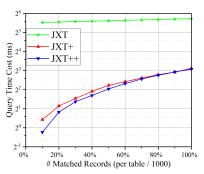

Figure 1: Storage Overhead Comparison

JXT JXT JXT JXT+ JXT+ JXT+ JXT+ JXT+ JXT+ JXT+ JXT+

Figure 2: Query Time (all matched)

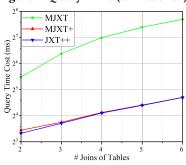

Figure 3: Query Time (partly matched)

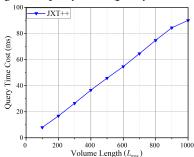

Figure 4: Setup Time Comparison

Figure 5: Query Time With Tables

Figure 6: Query Time With Volumes

and each table owns 65,535 rows and 11 attribute columns (including one record identifier column). In total, the dataset involves 393,210 rows and 60 attribute columns. All experiments are conducted on the same machine equipped with Intel i5-11500 2.70GHz CPU and 16GB RAM. To ensure precise cost measurement, all experiments are executed on the same device for both the client and server. The reported running times are the average values derived from 1000 experiments. Our source code is available at Github⁵

We will provide a complete evaluation in

will compare setup cost and query efficiency in JXT, JXT+, and JXT++. Specifically, we evaluate the setup cost for a single table because all three schemes don't need pre-computation at setup. And we evaluate the query efficiency over the joins of two tables for all schemes between the server and the client. Note that our scheme JXT++ supports query of the joins over multiple tables, in order to measure JXT++'s performance better, we program to extend JXT and JXT+ to support joins over three or more tables by using a naïve extension (i.e., MJXT and MJXT+). Interestingly, the extension will introduce sub-query result pattern (SRP) leakage but not influences the correctness of search. To be fair, we provide the evaluation on the query cost with different numbers of tables for MJXT, MJXT+ and JXT++.

In the following experiments, the XSet is implemented by Bloom filter with 2^{-64} false positive rate. The CSet in JXT+ is realized as the multi-map, and in JXT++ is realized as the XOR filter whose storage capacity is $\lfloor 1.23n \rfloor + \beta$. According to [15, 37], to guarantee the probability of success and relatively less storage, the parameter β of the XOR filter is set to 2 in our construction.

6.3 Evaluation and Comparison

Storage Cost. We note that in JXT, JXT+ and JXT++, the encrypted databases are built table-wise, and the total storage cost is essentially the sum of the overheads for each single table. Hence, we only focus on the storage cost for an individual table. Note that the server-side storage overhead of JXT is dominated by TSet and XSet, while CSet additionally is required for both JXT+ and JXT++.

To comprehensively evaluate the storage cost, we choose 1/2/3/4/5 attributes from 10 attributes as join attributes respectively as shown in Figure 1. For fairness, all join attributes in all three schemes are high-entropy columns, where the frequency of each join-attribute value is all 2. Intuitively, as the number of join attributes increases, these three schemes will use more storage on the server. Even though JXT+ and JXT++ need CSet additionally, our schemes outperform that of JXT, because JXT+ and JXT++ store fewer elements in TSet than JXT. Furthermore, as indicated in Table 3, we also explore the storage cost of the table with one join attribute when the join attribute has different entropy. We note that as the entropy of join attribute decreases, the elements in TSet and XSet of JXT++ become small, thus the storage cost of JXT++ will reduced. In particular, when the entropy of join attribute is set to 12, the storage cost of JXT is 53.2MB, while those of JXT+ and JXT++ are 27.1MB and 17.2MB, which brings a storage saving of 49% and 68%, respectively.

Setup Evaluation. We also discuss the setup time cost for each table with 1/2/3/4/5 join attributes respectively in 10 attributes. The cost of setup contains the generation of TSet and XSet for three schemes and CSet additionally for JXT+ and JXT++. Figure 4 shows that the setup cost of these three schemes increases when there is much more join attributes, and our schemes cost more time than JXT. The reason is that our schemes spend more time on the

 $^{^5} https://github.com/CDSecLab/MJXT.\\$

Table 3: Storage cost evaluation.

Scheme	$H(X)^6 = 16$	H(X) = 14	H(X) = 12
JXT	55.1MB	53.6MB	53.2MB
JXT+	39.5MB	29.6MB	27.1MB
JXT++	43.7MB	22.5MB	17.2MB

generation of CSet. Particularly, JXT++ costs the most setup time, since CSet of JXT++ is implemented by the XOR filter.

Query Evaluation. For a comprehensive evaluation of query costs, we run the experiments with various query results over the joins of two tables as shown in Figure 2 and Figure 3. Furthermore, we evaluate the query time of JXT++ in terms of different joins of tables and L_{max} called volume length in Figure 5 and Figure 6, respectively.

Firstly, we discuss the query cost of two tables when the retrieved TSet entries (i.e., matched records in TSet) *all* satisfy the query. The number of retrieved TSet entries is set as $1,000/2,000/\dots/10,000$ respectively for each query. As depicted in Figure 2, the query time cost of these three schemes increases as the number of matched records in TSet increases. We can also find that JXT+ and JXT++ are superior to JXT in query efficiency. Specifically, for the number of matched records is 1,000, JXT takes 61ms to fetch 1,000*2 identifiers and decrypt all of them, while JXT+ takes 11.2ms, a speedup of $5.5\times$, and JXT++ takes 9.7ms, a speedup of $6.3\times$. For the number of matched records is 10,000, JXT takes 4,651.5ms to fetch 10,000*2 identifiers and decrypt all of them, while JXT+ takes 89.9ms, a speedup of $51.7\times$, and JXT++ takes 85.7ms, a speedup of $54.3\times$.

Next, we also discuss the query cost of two tables but in different situations that the retrieved TSet entries (i.e., matched records in TSet) *partially* satisfy the query. The number of retrieved TSet entries is fixed as 1,000, and the final results is 10%/20%/.../100% of retrieved TSet entries. We expect to explore the impacts of the size of final query results. As shown in Figure 3, JXT is scarcely influenced by the size of final query results and costs more time than JXT+ and JXT++. The underlying reason is that JXT must execute the huge computation, that is, 1,000,000 times XOR operation and membership-test. While in our schemes, we only need to execute 1,000 times same computation and the identifiers will merely be retrieved in the situation that the records satisfy the query. In particular, for the size of final results is 100, JXT takes 46.2ms to fetch 100 * 2 identifiers and decrypt all of them, while JXT+ takes 1.4ms, a speedup of $33 \times$, JXT++ takes 0.9ms, a speedup of $51.3 \times$.

In order to further investigate the performance of JXT++, we evaluate query efficiency with the number of joins of tables and with the volume length L_{max} . In Figure 5, we evaluate the query time of MJXT, MJXT and JXT++ on the premise that the number of matching identifiers for each table is 1,000. It is indicated that the query time of all three schemes increases as the number of joined tables increases. The reason is straightforward; it needs more computation and retrieves more identifiers when there are more tables to be joined. It is found that JXT++ perform the best although it has the highest level of security. Subsequently, we also query two tables to retrieve 1,000 records for each table, but the matching records have total 10 kinds of join-attribute values, namely, the

frequency of each value is 100. As demonstrated in Figure 6, the query time of JXT++ is increasing linearly with the volume length L_{max} . In JXT++, the value L_{max} is used to hide the frequency of join-attribute values. When the value L_{max} increases, the server will retrieve much more encrypted identifiers and the percentage of dummy identifiers in the result as well as the decryption cost of the client both become larger. Hence, the value L_{max} can be seen as a trade-off of efficiency and security. We can observe an extreme case in Figure 6 when L_{max} reaches 1,000, the query time cost is approximately 90ms. Note that the size of each table's result from the server is 10,000, while there exists only 1,000 real encrypted identifiers. The results manifest that JXT++ is also practical, even with a stronger security level.

7 Conclusion

In this paper, we investigate secure join queries without join precomputation in encrypted relational database. We first present JXT+, a new equi-join query protocol over two tables without join precomputation, which can support joins of attributes with different names and achieve better query efficiency. We then design the *first* equi-join query protocol across three or more tables, dubbed JXT++, which enjoys joins of arbitrary attributes even low-entropy attributes, while providing a tunable query complexity. Furthermore, we implement our two protocols and perform a complete comparison with the state-of-the-art JXT. Experimental results demonstrate that both of our proposed schemes are superior to JXT in terms of query and storage efficiency while achieving more powerful functionality.

A Proof of Non-adaptive Security for JXT+

We prove this theorem by a sequence of games G_0,\ldots,G_7 . Each game begins with an Initialize routine that takes (DB, q) as input from the adversary \mathcal{A} , who finally outputs a bit as the game's output based on the routine's result. The first game G_0 has the identical distribution to "real-world" game $\mathbf{Real}_{\mathcal{A}}^{|XT+}(\lambda)$ and the final one G_7 can be simulated with leakage profile instead of the actual (DB, q). For simplicity, a sequence of Q non-adaptive join queries across two tables is denoted as $\mathbf{q}=(\mathbf{t}_1,\mathbf{t}_2,\mathbf{w}_1,\mathbf{w}_2,\mathbf{attr}_1^*,\mathbf{attr}_2^*)$, where each query $\mathbf{q}[i]=(\mathbf{t}_1[i],\mathbf{t}_2[i],\mathbf{w}_1[i],\mathbf{w}_2[i],\mathbf{attr}_1^*[i],\mathbf{attr}_2^*[i])$ is a two-table join query "Select inds From $\mathsf{Tab}_{\mathbf{t}_1[i]}$ and $\mathsf{Tab}_{\mathbf{t}_2[i]}$ Join on $\mathsf{attr}_1^*[i]=\mathsf{attr}_2^*[i]$ Where $\mathbf{w}_1[i]\wedge \mathbf{w}_2[i]$ ", for $1\leq i\leq Q$. In the following, we will provide the details of each game and formally prove the computational indistinguishability between them.

Game G_0 : This game is instantiated based on $\operatorname{Real}_{\mathcal{A}}^{\mathsf{JXT+}}(\lambda)$ with minor differences. Specifically, this game simulates the encrypted database EDB and the transcript Tr by running Initialize based on (DB, \mathbf{q}) selected by the adversary \mathcal{A} . (1) EDB = (TSet, XSet, CSet) is simulated exactly as EDBSetup(DB) described in the real game. (2) $\operatorname{Tr}[i] = ((\operatorname{STags}[i], \operatorname{xjointoken}_1[i], \operatorname{xjointoken}_2[i])$, ResCT[i], ResInd[i]) for each query i ($1 \le i \le Q$) is generated as in the real game, except that the plaintext result ResInd is derived from DB rather than from decrypting the encrypted search result ResCT. Thus, assuming no false positives, the distribution of G_0 matches $\operatorname{Real}_{\mathcal{A}}^{\mathsf{JXT+}}(\lambda)$, so we have

$$\Pr[G_0 = 1] \le \Pr[\text{Real}_{\mathcal{A}}^{\text{JXT+}}(\lambda) = 1] + \text{negI}(\lambda).$$

Game G_1 : In this game, the PRFs $F(K_z, \cdot)$, $F(K_w, \cdot)$, $F(K_r, \cdot)$, and $F(K_{enc}, \cdot)$ are replaced with the independent random functions or selections with the appropriate domain and range. Therefore, there exists an efficient adversary \mathcal{B}_1 such that

$$\left| \Pr[G_1 = 1] - \Pr[G_0 = 1] \right| \le 4 \cdot Adv_{F,\mathcal{B}_1}^{\mathsf{PRF}}(\lambda).$$

Game G_2 : This game is identical to game G_1 , except that the ciphertext ct is generated with an encryption of a string 0^{λ} instead of the actual record identifier used in the real game. Given that the number of encryption operations is polynomial, i.e., $poly(\lambda)$, an efficient adversary \mathcal{B}_2 can be constructed such that

$$\Big|\Pr[G_2=1] - \Pr[G_1=1]\Big| \leq poly(\lambda) \cdot Adv_{\mathsf{SK},\mathcal{B}_2}^{\mathsf{IND-CPA}}(\lambda).$$

Game G_3 : This game differs in the computation process but is distributionally identical to G_2 . Specifically, it precomputes all possible values for generating XSet, CSet, xjointoken₁, and xjointoken₂ and collects them in arrays H and Y. These include values present in XSet and CSet, all possible values for membership testing in XSet, and values for xjointoken₁ and xjointoken₂ that do not correspond to any potential matches. Then the corresponding values in XSet and CSet are selected from H, while xjointoken₁ and xjointoken₂ are computed by choosing values from either H or Y. Thus, we have

$$Pr[G_3 = 1] = Pr[G_2 = 1].$$

Game G₄: This game is exactly like G₃ except that each y in T and the values in H and Y arrays are choosen at randomly from $\{0, 1\}^{\lambda}$.

We claim that

$$Pr[G_4 = 1] = Pr[G_3 = 1].$$

Game G_5 : In this game, instead invoking the real TSetSetup and TSetGetTag to compute TSet and STags, they are generated by constructing a non-adaptive simulator \mathcal{S}_T on input $\mathcal{L}_T(DB, t_1, \mathbf{w}_1, \mathbf{attr}_1^*)$ and $T_{t_1}[\mathbf{w}_1||\mathbf{attr}_1^*]$. Therefore, a non-adaptive secure TSet instantiation ensures the existence of \mathcal{S}_T such that the following holds:

$$\left| \Pr[G_5 = 1] - \Pr[G_4 = 1] \right| \le Adv_{\mathcal{B}_5, \mathcal{S}_T}^{\mathsf{TSet}}(\lambda).$$

Game G_6 : This game modifies the access to the H and Y arrays to ensure compatibility with the final simulator using the leakage profile. When accessing H at $(w, attr^*, w^*)$ or Y at (w, u, c), the game first checks if that index will be accessed again. If so, it uses the existing value; if not, it substitutes a random value. Since those indices won't be reused, this change doesn't affect the distribution of the game. Notably, the Y array is only accessed once during transcript generation and can be replaced with random values, so leading to the removal of the Y array from this game.

Next, we describe the way of accessing the *H* array. The *H* array is accessed only during two processes: (1) XSet&CSetSetup: the generation of XSet and CSet, and (2) GenTrans: the generation of the transcript, specifically for xjointoken1 and xjointoken2.

The XSet&CSetSetup routine does not repeatedly access H, but some of them might be accessed by GenTrans. We observe that GenTrans reads indices such that $(\mathbf{w}_1[i] = w \vee \mathbf{w}_2[i] = w) \wedge w^* \in \{\text{val}^* : (\text{ind}_1, \text{attr}_1^*[i], \text{val}^*) \in \text{Tab}_{t_1[i]} \wedge (\text{ind}_2, \text{attr}_2^*[i], \text{val}^*) \in \text{Tab}_{t_2[i]} \wedge (\text{ind}_1, \mathbf{w}_1[i]) \in \text{Tab}_{t_1[i]} \wedge (\text{ind}_2, \mathbf{w}_2[i]) \in \text{Tab}_{t_2[i]} \}$ for a given query i. Therefore, we use the corresponding values from H at these indices in the generation of XSet and CSet and replace the others with random values.

In the GenTrans routine, we need to check for repeated index accesses, including positions read by XSet&CSetSetup or revisited by GenTrans itself. First, we determine which indices correspond to the final matches and access values from H at these positions. These values are clearly among those accessed by XSet&CSetSetup, so GenTrans tests for the same condition. Then, we observe that some positions are accessed twice in two different GenTrans calls. For some $i\neq j,\ w^*$ is an element of both $\{\mathrm{val}^*:(\mathrm{ind},\mathrm{w}_1[j])\in \mathrm{Tab}_{\mathsf{t}_1[j]} \land (\mathrm{ind},\mathrm{attr}_1^*[j],\mathrm{val}^*)\in \mathrm{Tab}_{\mathsf{t}_1[j]} \}$ and $\{\mathrm{val}^*:(\mathrm{ind},w_1)\in \mathrm{Tab}_{\mathsf{t}_1} \land (\mathrm{ind},\mathrm{attr}_1^*,\mathrm{val}^*)\in \mathrm{Tab}_{\mathsf{t}_1} \}$. For these repeated accesses determined by w^* , we use the values from H. In all other cases, GenTrans replaces the H accesses with random values.

Based on the above observations and discussion, we have

$$Pr[G_6 = 1] = Pr[G_5 = 1].$$

Simulator: This game constructs a simulator \mathcal{S} and takes the leakage profile $\mathcal{L}(\mathsf{DB},q)$ as an input, which consists of $\mathcal{L}_{\mathsf{JXT+}}(\mathsf{DB},q)$, $\mathcal{L}_{\mathsf{T}}(\mathsf{DB},t_1,w_1,\mathsf{attr}_1^*)$, and $\mathsf{T}_{t_1}[w_1||\mathsf{attr}_1^*]$. It finally outputs the simulated $\mathsf{EDB} = (\mathsf{TSet},\mathsf{XSet},\mathsf{CSet})$ and transcripts $\mathsf{Tr} = ((\mathsf{STags},\mathsf{xjointoken}_1,\mathsf{xjointoken}_2),\mathsf{ResCT},\mathsf{ResInd})$, which has same distribution as G_6 .

<u>TSet Simulation</u>: The non-adaptive simulator \mathcal{S}_T is invoked to generate TSet and STags based on $\mathcal{L}_T(\mathsf{DB}, \mathsf{t}_1, \mathsf{w}_1, \mathsf{attr}_1^*)$, and $\mathsf{T}_{\mathsf{t}_1}[\mathsf{w}_1||\mathsf{attr}_1^*]$, which has the same distribution as in G_6 . Note that $\mathsf{T}_{\mathsf{t}_1}[\mathsf{w}_1||\mathsf{attr}_1^*]$ can be computed by randomly selecting y from $\{0,1\}^\lambda$.

Next, we utilize the leakage $\mathcal{L}_{JXT_+}(DB, \mathbf{q}) = (n, RP, EP_1, EP_2, SP_1, JD)$ to simulate XSet and CSet, and then produce the transcript Tr. Before this, the simulator \mathcal{S} preprocesses some leakage to facilitate their use. Specifically, the simulator \mathcal{S} first generates two leakage variants \overline{RP} and \overline{EP}_2 based on the result pattern leakage RP and the equality pattern leakage \overline{EP}_2 , respectively.

- For each join query $\mathbf{q}[i]$ $(i \in [Q])$, $\overline{\mathsf{RP}}[i] = \{\mathsf{encode}(\mathsf{val}^*) : \mathsf{ind} \in \mathsf{RP}[i] \land (\mathsf{ind}, \mathsf{attr}_1^*[i], \mathsf{val}^*) \in \mathsf{Tab}_{\mathsf{t}_1}[i] \}$ is a multi-set of join-attribute values (in the randomized encoding version) for the record identifiers appearing in the final result $\mathsf{RP}[i]$ in the table $\mathsf{Tab}_{\mathsf{t}_1}[i]$.
- \overline{EP}_2 is the restricted equality pattern of w₂ and is also represented by an integer vector, which can be derived from EP₂ and JD. Specifically, we define \overline{EP}_2[i] = \overline{EP}_2[j] iff EP₂[i] = EP₂[j] and JD[i] ∩ JD[j] ≠ ∅ for i, j ∈ [Q].

<u>XSet and CSet Simulation</u>: The simulator S precomputes the H array by combining EP₁ with JD and $\overline{\text{EP}}_2$ with JD, encompassing all values $H[w, w^*]$ that may or may not be accessed, where w is from EP and w^* is from JD. Then the simulator uses the variant $\overline{\text{RP}}$ of result pattern leakage to select the corresponding values $H[w, w^*]$ that may appear in the result set and store them into XSet. Simultaneously, the simulator inserts $(H[w, w^*], ct)$ into CSet, where ct is the ciphertext of 0^{λ} .

Transcript Simulation: The simulator ${\cal S}$ computes the transcript $Tr[i] = ((STags[i],xjointoken_1[i],xjointoken_2[i]),ResCT[i],ResInd[i]),$ for $1 \le i \le Q$. Specifically, STags is simulated within TSet simulation, ResInd[i] can be derived from RP[i], and ResCT[i] is simulated by the server search subroutine as described in real game. Furthermore, we describe how to compute xjointoken1 and $xjointoken_2$. S collects the encoding of the join-attribute values for a given i as $R \leftarrow \overline{\mathsf{RP}}[i] \cup \bigcup_{j=1}^Q \mathsf{JD}[j] \cap \mathsf{JD}[i]$ and puts them in canonical order as $(\bar{w}_1^*, \bar{w}_2^*, ..., \bar{w}_{|R|}^*) \leftarrow R$. Since each index in R belongs to $\mathsf{DB}^{\mathsf{Join}}_{\mathsf{Tab}_{t_1}}(w_1)$, it follows $|R| \leq \mathsf{SP}_1[i]$. \mathcal{S} pads |R| up to $\mathsf{SP}_1[i]$ by setting $\bar{w}_k^* \leftarrow \bot$ for $k = |R| + 1, \ldots, \mathsf{SP}_1[i]$. The simulator then determines whether xjointoken is obtained from H array or random values. Specifically, for $c = 1, ..., SP_1[i]$, if $\bar{w}_c^* \neq \perp$, then xjointoken₁[c] and xjointoken₂[c] are computed by using $H[w, w^*] \oplus y$; otherwise, they are assigned random values from $\{0,1\}^{\lambda}$. In addition, $c = \mathsf{SP}_1[i] + 1, \ldots, T_{\max}$, we also select random values for xjointoken₁ [c] and xjointoken₂ [c]. Note that T_{max} is a upper bound to fix the number of xjointoken for simplicity. Thus, the distributions of xjointoken₁ and xjointoken₂ generated by the simulator are the same as those produced in G_6 .

In summary, the simulator \mathcal{S} with the leakage $\mathcal{L}(\mathsf{DB},q)$ generates a distribution identical to that of G_6 , so we complete the proof.

Algorithm 4 Game 0
